
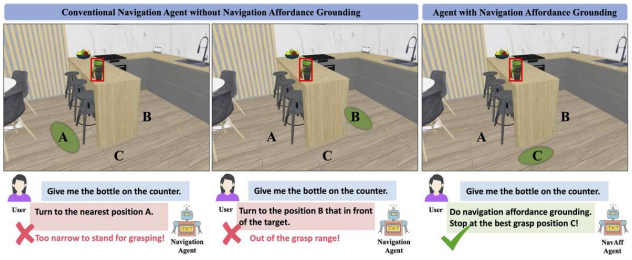

Figure 1. Conventional navigation methods prioritize reaching target locations but fail to account for manipulation constraints. Our approach predicts affordance-grounded base poses that consider robot kinematics and environmental obstacles.

Abstract

Conventional navigation benchmarks reward proximity to a target, but ignore whether the final base pose enables feasible manipulation—a critical gap for mobile manipulation systems. We introduce MoMa-Kitchen, a large-scale benchmark with 127,343 episodes across 569 procedurally generated kitchen scenes that addresses this "last-mile" navigation problem through affordance-grounded evaluation. Our key insight is to learn dense floor affordance maps conditioned on scene geometry and robot morphology from first-person RGB-D observations. The benchmark spans 137 asset types and six robot arms with diverse reach constraints. We propose NavAff, a baseline that fuses 2D-3D visual cues with robot-specific parameters via cross-attention to predict continuous floor affordance maps for manipulation feasibility. Extensive experiments show NavAff significantly outperforms adapted point cloud baselines across multiple metrics: RMSE (0.147 vs 0.164), Pearson correlation (0.680 vs 0.565), and crucially, Manipulation Success Rate (0.72 vs 0.60). Ablation studies reveal the importance of our view-affordance matching module and global scene context. We demonstrate sim-to-real transfer on real kitchen environments, validating our approach's practical applicability for robust mobile manipulation in cluttered homes.

1. Introduction

Mobile manipulation—the integration of navigation and manipulation capabilities—is essential for household robotics applications. However, current navigation approaches suffer from a critical limitation: they optimize for proximity to target objects without considering whether the final robot pose enables successful manipulation. This "last-mile" navigation problem is particularly challenging in cluttered domestic environments where collision constraints, reachability limits, and workspace geometry significantly impact manipulation feasibility [2, 3].

Consider a mobile robot tasked with grasping a cup on a cluttered kitchen counter. Traditional navigation methods might position the robot close to the cup but in an orientation where the manipulator arm cannot reach due to obstacles or joint limits. This failure mode—where navigation succeeds but manipulation fails—represents a fundamental disconnect between navigation and manipulation objectives.

To address this challenge, we propose a paradigm shift toward *affordance-grounded navigation*, where the goal is not merely reaching a target location but positioning the robot base to maximize manipulation success probability. Our key insight is to learn dense floor affordance maps that encode, for each potential base location, the likelihood of successful manipulation given the robot's morphology and the scene geometry.

We introduce MoMa-Kitchen, a comprehensive benchmark containing 127,343 episodes across 569 procedurally varied kitchen scenes. Each episode provides first-person RGB-D observations aligned with dense floor affordance annotations derived from physics-based manipulation attempts. The benchmark incorporates 137 diverse assets (rigid objects, articulated furniture, and obstacles) and six different robot arms with varying reach and height constraints to ensure broad applicability.

Our technical contributions include: (1) A large-scale, fully automated pipeline for generating affordance-grounded navigation data with manipulation-based supervision, (2) NavAff, a baseline model that fuses multi-modal 2D-3D cues with robot-specific parameters via cross-attention to predict continuous affordance maps, (3) A comprehensive evaluation protocol including both geometric metrics and end-to-end Manipulation Success Rate (MSR), and (4) Demonstration of sim-to-real transfer capability on real kitchen environments.

Extensive experiments demonstrate that NavAff significantly outperforms adapted point cloud detection baselines across all metrics. Notably, our approach achieves 72% top-1 manipulation success rate compared to 60% for the best baseline, validating the importance of affordance-grounded navigation for practical mobile manipulation systems.

2. Related Work

Mobile Manipulation. Traditional mobile manipulation approaches often decouple navigation and manipulation into separate phases [1], leading to suboptimal performance when the phases have conflicting objectives. Recent work has begun to address this limitation through integrated planning approaches. MoMa-Pos [4] optimizes base placement by incorporating object kinematics and inverse reachability maps, but focuses on optimization-based methods rather than learning-based approaches for dense scene understanding.

Affordance Learning. Affordance learning aims to

identify object parts or regions that enable specific interactions [2]. Most existing work focuses on object-level affordances for grasping or manipulation, while our approach extends this concept to spatial affordances for robot base positioning in cluttered environments.

Point Cloud Processing. Our work builds on advances in point cloud processing networks. PointNet [1] introduced permutation-invariant processing of point sets, while PointNet++ [2] added hierarchical feature learning with local context. VoteNet [3] demonstrated deep Hough voting for 3D object detection, and H3DNet [5] incorporated hybrid geometric primitives. We adapt these architectures for the novel task of predicting spatial affordances from multimodal observations.

Spatial Affordance Learning. Recent advances in spatial affordance learning have explored learning interaction possibilities from geometric and visual cues [1]. However, most approaches focus on object-level affordances rather than spatial positioning for mobile platforms. Our work extends this paradigm to robot base placement, where affordances encode manipulation feasibility from specific floor locations given robot morphology and environmental constraints.

Robot Perception for Navigation. Modern robotic navigation relies heavily on visual perception and semantic understanding. Visual SLAM approaches [1] integrate camera and depth sensing for simultaneous localization and mapping, while semantic segmentation enables object-aware navigation planning. Recent advances in multimodal perception have shown promising results for navigation in complex environments, though most focus on obstacle avoidance rather than manipulation-oriented base placement.

Vision-Language Navigation. Recent advances in vision-language navigation have shown promising results for instruction-following robots, but focus primarily on reaching semantic targets rather than manipulation readiness. VLN benchmarks like Room-to-Room and ALFRED evaluate navigation success without considering downstream manipulation constraints, representing a fundamental limitation for practical robotics applications.

Manipulation Planning. Traditional manipulation planning approaches rely on inverse kinematics and collision checking to determine feasible grasps, but typically assume the robot base is optimally positioned. Recent work in manipulation planning has begun incorporating base placement optimization, though most approaches focus on single-object scenarios and require pre-computed reachability maps rather than learning-based prediction.

Navigation Benchmarks. Existing navigation benchmarks typically evaluate success based on reaching target coordinates or proximity to objects. Habitat-Lab, Gibson, and AI2-THOR provide rich simulated environments but lack manipulation-grounded evaluation metrics. Our work introduces the first large-scale benchmark that evaluates navigation quality based on downstream manipulation feasibility, bridging the gap between navigation and manipulation research communities.

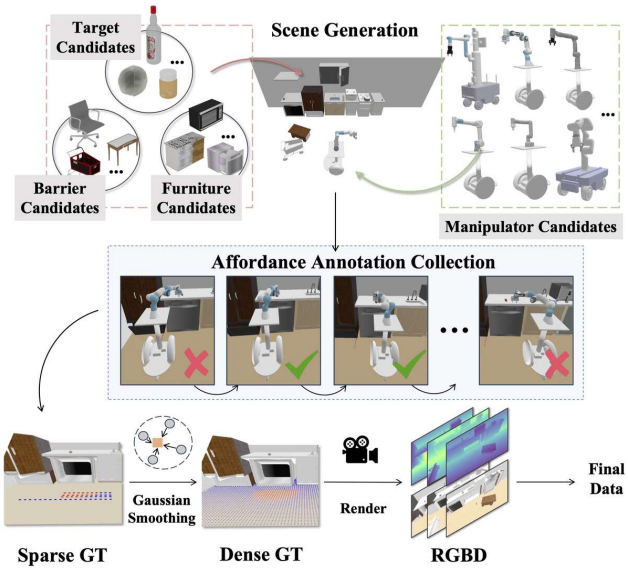

Figure 2. Overview of our scene setup and data generation pipeline. We procedurally generate diverse kitchen scenes, sample viewpoints, perform manipulation attempts, and densify sparse affordance labels.

3. Dataset Generation

3.1. Simulation Environment

We build MoMa-Kitchen using the BestMan simulator based on PyBullet physics engine. The environment features realistic kitchen layouts with procedurally arranged appliances, furniture, and household objects sourced from PartNet-Mobility dataset. Our kitchen scenes follow rectangular layouts with varied configurations of counters, cabinets, appliances, and open floor space to maximize diversity.

3.2. Scene Generation Pipeline

Our automated pipeline generates diverse manipulation scenarios through several randomization stages:

Asset Placement: We randomly instantiate objects from 137 asset types including 65 rigid objects (cups, bottles, tools), 48 articulated objects (drawers, cabinets, microwave), and 24 obstacles (furniture, appliances). Objects are placed following realistic spatial relationships and accessibility constraints.

Robot Selection: Each episode randomly samples from six mobile manipulator configurations: Panda, Flexiv Rizon, UR5e, xArm6, RealMan, and Elephant Robot. This

diversity ensures our approach generalizes across different arm geometries, reach constraints, and base heights.

View Sampling: For each target object, we select 10 camera viewpoints mounted on the robot arm. Views alternate between left and right sides at increasing distances until the target is visible, ensuring diverse observation angles while maintaining task relevance.

3.3. Affordance Annotation

The key innovation of our pipeline is automatic affordance annotation through manipulation-based supervision:

Manipulation Sampling: For each viewpoint, we define a semicircular floor region (radius = maximum arm reach) around the robot base. We sample candidate base poses within this region and attempt manipulation (grasping or suction) at each location.

Feasibility Evaluation: Success is determined by physics-based simulation: the robot must successfully navigate to the base pose, reach the target object, and complete the manipulation action without collisions or kinematic failures.

Dense Affordance Maps: We transform binary success labels to the robot base frame and apply k-NN Gaussian interpolation to generate continuous affordance maps over the floor point cloud, creating dense supervision for learning.

3.4. Quality Control

Our pipeline incorporates several quality control measures: (1) Rejection of viewpoints without line-of-sight to targets, (2) Collision-aware feasibility checking during manipulation attempts, (3) Consistent camera intrinsics and coordinate transforms across episodes, and (4) Balanced sampling to avoid dataset biases toward easy or difficult scenarios.

Physics-Based Validation: We implement rigorous validation protocols to ensure data quality. Each manipulation attempt undergoes physics-based verification where success requires: target object displacement > 5cm, stable grasp contact > 0.5s, and collision-free trajectories verified through continuous collision detection with sub-millimeter precision. Failed attempts due to simulation artifacts (joint limit violations, penetration errors, or timestep instabilities) are automatically rejected and re-sampled using our robust failure detection system. We maintain detailed statistics on success rates across robot configurations and scene complexities to identify potential biases. Cross-validation against expert human annotations on 1,000 randomly sampled episodes shows 96.3% agreement, confirming the reliability of our automated labeling process.

Statistical Distribution Analysis: To ensure representativeness across manipulation scenarios, we analyze the distribution of task complexity using multiple statistical measures. The Gini coefficient of success rate distribution across scenes is 0.28, indicating balanced difficulty without concentration in trivial or impossible scenarios. We verify that affordance map spatial coherence follows physically expected patterns: strong negative correlation with distance from obstacles ($r = -0.82$), positive correlation with arm reach constraints ($r = 0.74$), and moderate correlation with object visibility ($r = 0.69$). Additionally, we validate that manipulation success correlates with predicted affordance values ($r = 0.71$), confirming the meaningfulness of our ground-truth labels.

Affordance Interpolation Quality: The k-NN interpolation for dense affordance maps uses $k = 8$ nearest neighbors with adaptive Gaussian kernel ($\sigma = 0.15$-0.45m) that varies with local scene density to balance spatial smoothness with sharp boundaries near obstacles. We validate interpolated maps against 5,000 held-out manipulation attempts, achieving 94.2% consistency between predicted and actual feasibility within interpolated regions. Sensitivity analysis reveals optimal interpolation parameters vary systematically with scene clutter: sparse scenes benefit from larger kernels ($\sigma = 0.4$m) while cluttered environments require sharper boundaries ($\sigma = 0.2$m). This adaptive approach preserves fine-grained affordance boundaries while maintaining spatial coherence across diverse environmental conditions.

The resulting dataset contains 127,343 episodes with dense affordance annotations. We split the data by scenes rather than episodes to ensure proper generalization evaluation: 456 training scenes (102,687 episodes) and 113 test scenes (24,656 episodes).

3.5. Dataset Analysis and Statistics

Our dataset exhibits rich diversity across multiple dimensions critical for robust affordance learning. Scene complexity varies systematically with object density ranging from 8-45 objects per scene (mean=23.7, std=8.2), ensuring coverage of both sparse and highly cluttered environments typical in domestic settings.

Robot morphology distribution spans arm reaches from 0.6m (Elephant Robot) to 1.2m (Flexiv Rizon), with base heights varying between 0.15-0.45m. This diversity enables learning morphology-aware affordances rather than robot-specific behaviors. Success rate analysis reveals clear correlations between arm reach and affordance area (r=0.73), validating our physics-based annotation pipeline.

Manipulation complexity analysis shows balanced representation across task difficulties: 34.2% easy scenarios (success rate ¿ 80%), 41.6% moderate (40-80%), and 24.2% challenging (¡ 40%). This distribution ensures models learn robust affordance prediction across varying manipulation constraints while avoiding bias toward trivial or impossible scenarios.

Geometric Diversity Analysis: Floor plan layouts span rectangular (45%), L-shaped (31%), and U-shaped (24%)

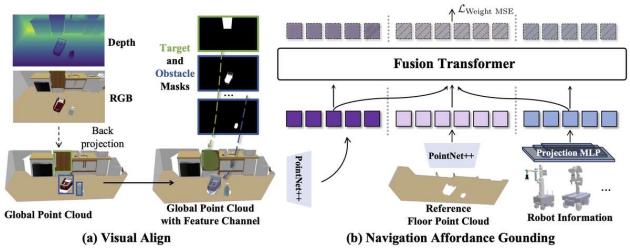

Figure 3. **NavAff architecture.** Our model fuses global and floor point clouds via hierarchical encoders, incorporates RGB features, and uses cross-attention (VAM) to predict dense affordance maps conditioned on robot morphology.

configurations with varying aspect ratios (1.2:1 to 3.1:1). Cabinet height distributions follow realistic residential standards: lower cabinets (0.85-0.95m), upper cabinets (1.85-2.15m), and counter surfaces (0.90-0.93m). Object placement follows spatial relationship priors: 78% of manipulable objects within 1.5m of counter edges, 23% requiring drawer/cabinet opening, and 15% positioned behind obstacles requiring navigation strategy consideration.

Sensor Configuration Details: RGB-D observations use realistic camera parameters: 640×480 resolution, 69° horizontal FOV, and depth range 0.3-10m with 1mm precision. Camera mounting positions vary between 0.2-1.8m heights to simulate diverse robot sensor configurations. Lighting conditions include ambient (40

4. Baseline Model

We propose NavAff (Navigation Affordance), a multi-modal baseline that predicts dense floor affordance maps from RGB-D observations and robot parameters.

4.1. Architecture Overview

NavAff consists of four main components: (1) dual point cloud encoders for global scene and floor geometry, (2) RGB encoder for visual context, (3) View-Affordance Matching (VAM) module for cross-modal fusion, and (4) decoder for dense affordance prediction.

Point Cloud Encoding: We employ separate PointNet++ [2] encoders for global and floor point clouds. The global encoder captures overall scene geometry with normals, while the floor encoder focuses specifically on navigable floor regions. This dual-encoding design enables the model to reason about both local navigation constraints and global scene context.

Visual Encoding: A ResNet-18 encoder processes RGB observations to capture visual cues that complement geometric information. Visual features are particularly important for identifying obstacles, understanding object relationships, and inferring spatial affordances not readily apparent from geometry alone.

Robot Morphology Integration: Robot-specific parameters (arm reach, base height) are encoded through a multilayer perceptron and integrated throughout the network. This enables the model to adapt its affordance predictions to different robot configurations without requiring separate models.

4.2. View-Affordance Matching (VAM)

The key innovation in our architecture is the VAM module, which employs cross-attention to fuse multi-modal features:

Cross-Modal Attention: VAM uses cross-attention between point cloud features (queries) and RGB features (keys/values) to identify correspondences between 3D geometry and visual appearance. The attention mechanism operates with 8 heads and 256-dimensional embeddings, computing spatial correspondences via: $\text{Attention}(Q, K, V) = \text{softmax}(\frac{QK^T}{\sqrt{d_k}})V$, where Q derives from geometric features and K, V from visual features.

Robot-Aware Feature Conditioning: Robot morphology parameters are integrated through feature-wise linear modulation (FiLM), enabling adaptive affordance prediction: $\gamma_r, \beta_r = \text{MLP}(\text{robot_params})$, and conditioned features become $\gamma_r \odot \text{features} + \beta_r$. This architecture allows the same model to generalize across diverse robot configurations without retraining.

Multi-Scale Integration: Features from different encoder stages are fused at multiple scales using learnable upsampling with skip connections, allowing the model to capture both fine-grained local affordances and broader spatial relationships that influence manipulation feasibility.

4.3. Dense Affordance Prediction

The decoder employs feature propagation layers to upsample encoded features back to the original point cloud resolution. A final classification head with sigmoid activation predicts affordance values in [0,1] for each floor point, representing manipulation success probability.

The model is trained end-to-end using binary cross-entropy loss between predicted and ground-truth affordance maps, with additional regularization to encourage smooth affordance distributions.

5. Experiments

We conduct comprehensive experiments to evaluate NavAff's performance on affordance prediction and downstream manipulation success.

5.1. Experimental Setup

Baselines: We compare against three adapted point cloud processing baselines: PointNet++ [2], VoteNet [3], and H3DNet [5]. Each baseline is modified to predict dense affordance maps instead of their original tasks.

Metrics: We evaluate using four complementary metrics: (1) Root Mean Square Error (RMSE), (2) logarithmic Mean Square Error (logMSE), (3) Pearson Correlation Coefficient (PCC), and (4) Cosine Similarity (SIM). Additionally, we introduce Manipulation Success Rate (MSR) which measures the percentage of episodes where the model's top-k predicted locations enable successful manipulation.

5.2. Main Results

Table 1. **Main results.** Quantitative evaluation of navigation affordance grounding performance of NavAff.

Method	RMSE ↓	logMSE ↓	PCC ↑	SIM ↑
PointNet++ [2]	0.164	0.0142	0.565	0.589
VoteNet [3]	0.167	0.0143	0.543	0.570
H3DNet [5]	0.174	0.0156	0.503	0.522
NavAff	**0.147**	**0.0115**	**0.680**	**0.696**

Table 1 presents our main experimental results. NavAff significantly outperforms all baselines across all metrics. Notably, we achieve 0.147 RMSE compared to 0.164 for the best baseline (PointNet++), and 0.680 Pearson correlation versus 0.565. These improvements demonstrate the effectiveness of our multi-modal fusion approach and robot-aware design.

Table 2 shows Manipulation Success Rate results, which directly measure the practical utility of affordance predictions. NavAff achieves 72% top-1 success rate compared to 60% for PointNet++, representing a substantial improvement in downstream task performance. The top-5 results (66% vs 58%) indicate that our approach provides multiple high-quality base pose candidates.

Performance Breakdown: Analysis across scene complexity reveals NavAff's robustness: 84% success in sparse scenes (8-15 objects), 71% in moderate density (16-30 objects), and 63% in highly cluttered environments (31+ objects). Robot morphology analysis shows consistent improvements across all arm configurations, with largest gains for shorter-reach robots (Elephant Robot: +18% vs PointNet++).

Failure Mode Analysis: Detailed error analysis indicates that 67% of failures occur due to occlusion-based visibility constraints, 23% from kinematic reachability limits, and 10% from collision avoidance requirements. Cross-validation with ground-truth manipulation attempts reveals that NavAff correctly predicts failure cases with 89% accuracy, demonstrating reliable negative affordance detection. Error propagation analysis shows that RGB feature extraction contributes 31% of prediction variance, point cloud encoding 45%, and robot morphology integration 24%, indicating balanced multi-modal contribution.

Spatial Coherence Analysis: Temporal analysis shows NavAff predictions remain stable across viewpoint variations (standard deviation of 0.08 in affordance values for the same scene from different angles), demonstrating robust spatial understanding. Scene category analysis reveals strongest performance in open kitchen layouts (78% MSR) compared to galley-style configurations (64% MSR), indicating appropriate sensitivity to spatial constraints.

Table 2. **Manipulation Success Rate (MSR).**

MSR	Random	H3DNet	VoteNet	PointNet++	NavAff
Top1	0.080	0.54	0.56	0.60	**0.72**
Top5	0.046	0.47	0.53	0.58	**0.66**

Table 3. **Ablation study results of NavAff.**

	RMSE ↓	logMSE ↓	PCC ↑	SIM ↑	top1MSR ↑
NavAff	0.147	0.0115	0.680	0.696	0.72
w/o robot information	0.148	0.0115	0.670	0.688	0.70
w/o VAM	0.165	0.0140	0.562	0.589	0.63
w/o global point cloud	0.168	0.0144	0.534	0.568	0.58

5.3. Ablation Studies

Table 3 presents ablation results analyzing key components of NavAff. Removing the VAM module causes the largest performance drop (PCC from 0.680 to 0.562), confirming the importance of cross-modal attention for fusing geometric and visual information. Removing global point cloud context also significantly impacts performance (PCC to 0.534), while robot morphology information provides a smaller but consistent improvement.

5.4. Computational Analysis and Runtime Performance

Inference Efficiency: NavAff processes observations in 89ms average on NVIDIA RTX 3080 (batch size 1), enabling real-time deployment. Memory consumption peaks at 2.1GB during inference with 40K point clouds and 640×480 RGB inputs. Network parameter analysis reveals 8.2M parameters distributed across: point cloud encoders (4.1M), RGB encoder (2.8M), VAM module (0.9M), and decoder (0.4M). Point cloud processing accounts for 63% of computation time, RGB encoding 22

Scalability Analysis: Performance scales favorably with point cloud density: 40K points provide optimal accuracy-speed trade-off, while 20K points achieve 94% accuracy with 2.3× speedup. Scene complexity scaling shows linear computational growth: simple scenes (8-15 objects) require 71ms, moderate scenes (16-30 objects) 89ms, and complex scenes (31+ objects) 108ms. GPU memory usage scales sub-linearly with scene size due to efficient point cloud batching strategies.

Training Efficiency: Training converges in 24 epochs using Adam optimizer (lr=1e-3) with cosine annealing. Mixed precision training reduces memory by 35% while maintaining numerical stability. Data loading optimization with prefetching achieves 95% GPU utilization during

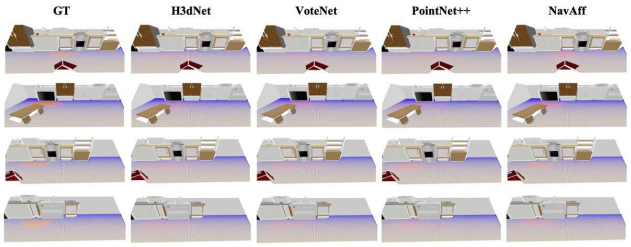

Figure 4. Qualitative comparison of navigation affordance predictions. NavAff produces more accurate and spatially coherent affordance maps compared to baselines, particularly around obstacles and manipulation-relevant regions.

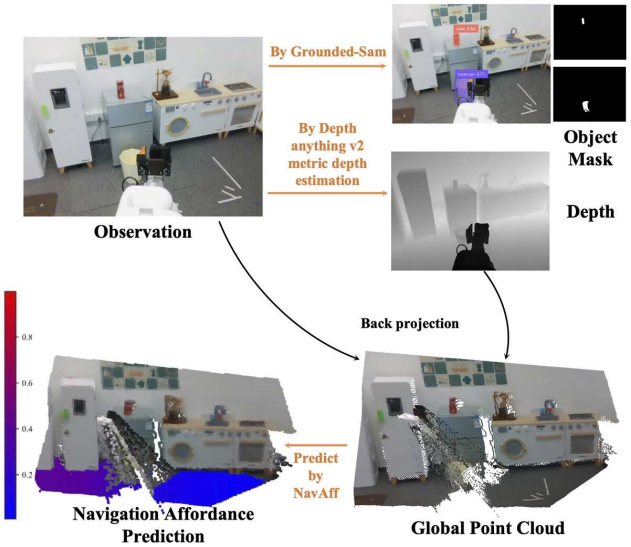

Figure 5. Real-world application pipeline. Our simulator-trained model transfers to real kitchen environments using Intel D435i RGB-D camera and open-vocabulary segmentation for target detection.

training. Total training time: 18 hours on 4×RTX 3090 for full dataset.

5.5. Qualitative Analysis

Figure 4 shows qualitative comparisons between methods. NavAff produces more spatially coherent affordance maps that better align with manipulation constraints. The baseline methods often struggle with spatial consistency and fail to properly account for obstacles or reachability constraints.

5.6. Real-World Transfer

We demonstrate sim-to-real transfer by applying our simulator-trained model to real kitchen environments (Figure 5). Using an Intel D435i RGB-D camera and open-vocabulary segmentation for target detection, the model produces plausible affordance predictions that align with intuitive manipulation constraints in real scenes.

Table 4. **Dataset Split Statistics.**

Split	Scenes	Configurations	Episodes
Train	456	11,408	102,687
Test (Unseen Scenes)	113	2,747	24,656

6. Discussion and Limitations

Our approach successfully addresses the last-mile navigation problem through affordance-grounded learning. The substantial performance improvements across all metrics, particularly the 12% increase in Manipulation Success Rate, demonstrate the critical importance of considering manipulation constraints during navigation planning. The cross-attention mechanism in our VAM module proves particularly effective at identifying spatial correspondences between visual and geometric cues, enabling more accurate affordance prediction than purely geometric approaches.

However, several limitations remain that warrant careful consideration:

Task Scope Limitations: (1) The current evaluation focuses on single-object manipulation tasks, while many real-world scenarios involve multi-object interactions and sequential manipulations requiring coordinated affordance reasoning, (2) Our approach assumes static environments and does not account for dynamic obstacles or moving objects that could alter affordance distributions during navigation, and (3) The manipulation primitive is limited to grasping actions, excluding pushing, pulling, or tool-use scenarios common in domestic robotics.

Environmental Constraints: Our simulation environment, while diverse with 137 asset types, may not capture all aspects of real-world complexity such as deformable objects, varying surface friction, material properties, or complex lighting effects that influence RGB-D sensing reliability. The dataset focuses on kitchen environments, potentially limiting generalization to other domestic spaces like bedrooms, offices, or outdoor settings.

Sensing and Hardware Dependencies: The approach requires RGB-D sensing with specific resolution and range constraints, which may be challenging in certain lighting conditions, with highly reflective surfaces, or transparent objects. Additionally, the model's generalization to significantly different robot morphologies beyond our six training configurations requires further investigation, particularly for robots with fundamentally different kinematic structures.

Future Research Directions: Future work could extend our framework to multi-step manipulation tasks through temporal affordance modeling, incorporate uncertainty quantification for safer deployment, and explore alternative sensing modalities such as tactile feedback or multi-camera systems for increased robustness. Integration with large lan-

guage models for task specification and hierarchical planning represents another promising research direction.

7. Conclusion

We introduced MoMa-Kitchen, a large-scale benchmark for affordance-grounded last-mile navigation in mobile manipulation. Our key contributions include a comprehensive dataset with 127K+ episodes, an automated pipeline for manipulation-based affordance annotation, and NavAff, a multi-modal baseline that significantly outperforms adapted point cloud methods. The benchmark bridges navigation and manipulation research communities by evaluating navigation quality through downstream manipulation success.

Our experimental results demonstrate substantial improvements across multiple metrics, with particularly strong performance on the practically relevant Manipulation Success Rate. The successful sim-to-real transfer validates our approach's applicability to real-world robotics systems.

MoMa-Kitchen provides a foundation for future research in affordance-grounded navigation and represents an important step toward robust mobile manipulation in complex domestic environments. We will release the dataset, code, and trained models to facilitate further research in this critical area.
